Abstract
Vibration analysis that is the main conditions monitoring techniques for machinery maintenance and fault diagnosis, in rotating parts of tractor MF-285 for optimizing them is important. Practical experience has shown that this technique in a machine condition monitoring program provides useful reliable information, bringing significant cost benefits to industry. The objective of this study is to investigate the correlation between vibration analysis and fault diagnosis tractor gearbox. This was achieved by vibration analysis and investigating different operating conditions of tractor (M-F) gearbox. This gearbox coupled to the electromotor that was initially run under normal operating conditions and its speed was at two levels, 500 and 1000 RPM respectively. Even tooth in a gearbox is alternately meshing and detaching during its operation and the loading condition of the tooth is alternately changing. Hence, the gear conditions were considered to be normal gearbox and worn and broken-teeth gears faults with the aim of fault detection and identification. Vibration data was collected from the inspected gearbox and are used for compare with vibration spectra in normal condition of healthy machine, in order to quantify the effectiveness of the Vibration condition monitoring technique. The results from this study have given more understanding on the dependent roles of vibration analysis in predicting and diagnosing machine faults.

Keywords: Vibration condition monitoring, Gearbox, Fault diagnosis

1. Introduction
Tractor, as the most important agricultural machinery, has main share in planting, retaining and harvesting operations and then in mechanization sector. Hence, in order to reach sustainable agricultural and to increase mechanization level quality and manufacturing technology of this agricultural machinery and also its quantity must be reached to optimum level. Above statements show the importance of condition monitoring in gearbox of tractor MF-285 for optimizing them. In this regard, vibration condition monitoring in tooth gears of this tractor was studied. For years, condition monitoring of power transmission has been deemed imperative. Thus, gearboxes, the core of power transmission, have received considerable attention in the field of condition monitoring and fault diagnosis. In particular, gear localized defects have been extensively studied, since a large percent (60%) of gearbox damages are due to gear faults, which in turn are mostly initiated by localized defects. Vibrations externally measured on a gearbox have been used to monitor the operating condition of the gearbox and diagnose the fault, if there is any, without interfering with the normal operation. The most common method employed for examining mechanical vibration is spectral analysis. Condition monitoring and fault diagnostics is useful for ensuring the safe running of machines [Peng and Chu, 2004]. Vibrations signals are often used for fault signals diagnosis in mechanical systems since them often carry dynamic information from mechanical elements. These mechanical signals normally consist of a combination of the fundamental frequency with a narrowband frequency component and the harmonics. Most of these are related to the revolutions of the rotating system since the energy of vibration is increased when a mechanical element is damaged or worn. Some of the conventional techniques used for fault signals diagnosis include power spectra in time domain or frequency
gear mesh frequency. The gear mesh frequency is calculated via equation 1.

\[ \text{GMF} = \text{No.ofTeeth} \times \text{RPM} \]  

The corresponding spike at this frequency generally amplifies as gear damage increases [Andy et al, 2003].
3). Measurement values and mean of them were higher than the RMS value of gearbox in healthy condition. Figure 4 (at 500 rpm) and figure 5 (at 1000 rpm) showed the overall vibrations of worn and broken gear condition. As can be seen in figures, the prominent frequency peak occurred with high accuracy near the predicted value of gear mesh frequency, as shown in Table 2.

Vibration analysis technique has been used to assess the condition of the gearbox and diagnose any problems of that. The results from vibration analysis of our experimental research indicate our defaults those made in our gearbox. Vibration analysis of gearbox discovered the worn and broken teeth in gears. The correlation between the vibration analysis and fault diagnosis was excellent as vibration technique was able to pick up on different issues, thus presenting a broader picture of the machine condition. Vibration analysis detected a continuing gear defect along with a possibility of mechanical faults of the outer casing from assembly. Vibration analysis technique was capable in covering a wider range of machine diagnostics and faults within the gearbox.

4. Conclusions

The results clearly indicate a significant variation in vibration trend as a function of operating conditions. The experimental results demonstrated that the vibration monitoring rig modeled various modes of machine failure was indeed capable of both independently and simultaneously generate common machine faults. In this research we have been made an experimental test system that we were able to perform practical tests on the constructed rig to confirm the expected theoretical frequencies that we needed. This research was offered complementary strengths in root cause analysis of machine failure, and natural allies in diagnosing machine condition. It reinforces indications correlation between vibration condition monitoring and fault diagnosis for gearbox. Both amplitude of the dominating peak and its location along the frequency axis changes in various conditions of gear. The data indicate that it is not possible to conclude that the cause of real world machinery malfunction is fault gear just by looking at a single vibration spectrum at an operating condition. A careful examination is essential to differentiate fault gear from other sources of vibration. The corresponding stress will depend upon the stiffness of the machine structure. The frequencies of peak vibration amplitude, set locations and directions were inconsistent even with speed and coupling held constant. Increased speed also caused increased peak vibration with frequency shifts that did not correlate with the speed. For predictive maintenance applications where the goal is machinery health monitoring, it is sufficient to realize that the problem is complex. One can routinely trend the vibration spectra until it becomes severe. But for root cause analysis, one must exercise caution and perform a detailed analysis. Obviously, the rules provided in training courses and wall charts are doubtful at best.
